

# Data representation

## IGCSE Computer Science

### Why computers use binary

A computer can only work with two states: on and off. You write these as 1 and 0. A system that uses only two digits 数字 is called **binary** 二进制 (base 2).

*Computers represent all data — numbers, text, sound and images — as binary strings of 0s and 1s*

Every kind of data 数据 — numbers, text, sound and images — must be changed into binary before a computer can use it. The computer processes this binary using **logic gates** 逻辑门, and stores it in **registers** 寄存器 (small, fast stores inside the processor 处理器).

*A microprocessor holds millions of tiny transistors, each a switch that is on (1) or off (0) — the physical basis of binary*

## Number systems

A **number system** 数制 is a way of writing numbers using a fixed set of digits. You need three of them.

| System      | Base | Digits used  |
|-------------|------|--------------|
| Denary      | 10   | 0–9          |
| Binary      | 2    | 0 and 1      |
| Hexadecimal | 16   | 0–9 then A–F |

- **denary** 十进制 is the normal counting system (also called decimal).
- **binary** uses only 0 and 1.
- **hexadecimal** 十六进制 (hex) uses sixteen digits: 0–9, then A, B, C, D, E, F stand for 10, 11, 12, 13, 14, 15.

The **base** 基数 tells you how many different digits a system uses.

## Place value

Each column in a number has a **place value** 位值. In binary the place values double from right to left. For an 8-bit number they are:

128 64 32 16 8 4 2 1

|             |     |    |    |    |   |   |   |   |
|-------------|-----|----|----|----|---|---|---|---|
| place value | 128 | 64 | 32 | 16 | 8 | 4 | 2 | 1 |
| bits        | 1   | 0  | 0  | 1  | 0 | 1 | 1 | 0 |

$$150 = 128 + 16 + 4 + 2 \Rightarrow 10010110$$

*An 8-bit place-value chart: the 1s sit under the values that add up to 150*

One **bit** 位 is a single 0 or 1. Eight bits make one **byte** 字节. Four bits (half a byte) is a **nibble** 半字节.

## Converting between number systems

**Denary** → **binary**. Write the place values. Put a 1 under each value you need so they add up to your number; put 0 under the rest.

Example: change denary 150 to binary.  $150 = 128 + 16 + 4 + 2$ .

|     |    |    |    |   |   |   |   |
|-----|----|----|----|---|---|---|---|
| 128 | 64 | 32 | 16 | 8 | 4 | 2 | 1 |
| 1   | 0  | 0  | 1  | 0 | 1 | 1 | 0 |

So  $150 = 10010110$ .

**Binary** → **denary**. Add the place values where there is a 1.  $10010110 = 128 + 16 + 4 + 2 = 150$ .

**Hexadecimal** → **binary**. Change each hex digit into its own 4-bit group (a nibble).

Example: hex F08.  $F = 1111$ ,  $0 = 0000$ ,  $8 = 1000$ , so  $F08 = 1111\ 0000\ 1000$ .

one hex digit = one nibble (4 bits)

*Each hex digit maps to its own 4-bit nibble —  $F08 = 1111\ 0000\ 1000$*

**Binary** → **hexadecimal**. Group the bits into nibbles of 4, starting from the right. Change each nibble to one hex digit.

**Denary → hexadecimal.** The easy way is to change to binary first, then binary to hex.

This table helps with the hex letters:

| Denary | Binary | Hex |
|--------|--------|-----|
| 10     | 1010   | A   |
| 11     | 1011   | B   |
| 12     | 1100   | C   |
| 13     | 1101   | D   |
| 14     | 1110   | E   |
| 15     | 1111   | F   |

Cambridge questions use binary numbers up to 16 bits long.

**Worked example.** Convert denary 100 to 8-bit binary, then to hexadecimal.

$100 = 64 + 32 + 4$ , so the binary is 01100100. Splitting into nibbles, 0110 0100 = 6 and 4, so the hexadecimal is 64.

## Why hexadecimal is used

Hex is shorter than binary and easier for people to read and write. One hex digit replaces 4 binary digits, so you make fewer mistakes. The value does not change — hex is just a shorter way to show the same binary.

Computer scientists use hex for:

- MAC addresses and IPv6 addresses
- colour codes in HTML (for example #FF0000 is red)
- **memory addresses** 内存地址 and error codes
- showing the contents of memory (a “memory dump”)

## Binary addition

You can add two 8-bit binary numbers, column by column from the right, just like denary. The rules for one column are:

| A | B | Result bit | Carry |
|---|---|------------|-------|
| 0 | 0 | 0          | 0     |
| 0 | 1 | 1          | 0     |
| 1 | 0 | 1          | 0     |
| 1 | 1 | 0          | 1     |

When a carry also comes in,  $1 + 1 + 1 = 1$  with a carry of 1.

Example: add 01110110 (118) and 00110000 (48).

```

  0 1 1 1 0 1 1 0   (118)
+ 0 0 1 1 0 0 0 0   (48)
-----
  1 0 1 0 0 1 1 0   (166)

```

|   |         |       |   |   |   |   |   |   |     |
|---|---------|-------|---|---|---|---|---|---|-----|
|   | carries | 1     | 1 | 1 |   |   |   |   |     |
|   |         | 0     | 1 | 1 | 1 | 0 | 1 | 1 | 0   |
|   |         |       |   |   |   |   |   |   | 118 |
| + |         | 0     | 0 | 1 | 1 | 0 | 0 | 0 | 0   |
|   |         |       |   |   |   |   |   |   | 48  |
|   |         | <hr/> |   |   |   |   |   |   |     |
|   |         | 1     | 0 | 1 | 0 | 0 | 1 | 1 | 0   |
|   |         |       |   |   |   |   |   |   | 166 |

*Adding column by column; the carries ripple to the left.  $118 + 48 = 166$*

## Overflow

An 8-bit register can hold denary values from 0 to 255 only. If an addition gives a result above 255, the answer needs a 9th bit. The register cannot hold this extra bit, so it is lost. This is called **overflow** 溢出 (an overflow error). It happens when a value goes outside the limit the register can store.

Example:  $11001000$  (200) +  $01001000$  (72) = 272. In binary that is  $1\ 00010000$ , which needs 9 bits. The leading 1 will not fit in 8 bits, so the stored answer is wrong.

$200 + 72 = 272$ , but 272 needs **9 bits**:

stored answer =  $00010000 = 16$ , **not** 272 - this is **overflow**

*Adding 200 and 72 needs 9 bits, but an 8-bit register drops the ninth, so the answer is wrong*

# Logical binary shift

A **logical binary shift** 逻辑二进制移位 moves all the bits left or right by a number of places.

- Bits that move off the end of the register are **lost**.
- **Zeros** are added at the empty end.

A **left shift** multiplies the number by 2 for each place moved. A **right shift** divides it by 2 for each place; the right-most bits (the **least significant bit(s)** 最低有效位) are lost.

Example: left shift 00110101 (53) by 2 places.

```
start:          0 0 1 1 0 1 0 1
left shift 2:    1 1 0 1 0 1 0 0
```

*A left shift of 2: every bit moves 2 places left, the top bits are lost and zeros fill the right*

The result is 11010100 (212), which is  $53 \times 4$ . The two left-most bits were lost and two zeros came in on the right. If a 1 is pushed off the end, that information is gone for good.

## Two's complement

So far the numbers were positive. **Two's complement** 补码 lets an 8-bit register hold negative numbers too.

In two's complement, the left-most bit (the **most significant bit** 最高有效位, or MSB) has a *negative* place value:

-128 64 32 16 8 4 2 1

- If the MSB is 0, the number is positive.
- If the MSB is 1, the number is negative.

**To make a positive number negative:** write the positive binary, flip every bit ( $0 \leftrightarrow 1$ ), then add 1.

Example: make  $-40$ .

- $+40 = 00101000$
- flip the bits =  $11010111$
- add 1 =  $11011000$

So  $-40 = 11011000$ . Check by adding the place values:  $-128 + 64 + 16 + 8 = -40$ .

|             |                        |    |    |    |   |   |   |   |
|-------------|------------------------|----|----|----|---|---|---|---|
|             | sign bit<br>(negative) |    |    |    |   |   |   |   |
| place value | −128                   | 64 | 32 | 16 | 8 | 4 | 2 | 1 |
| bits        | 1                      | 1  | 0  | 1  | 1 | 0 | 0 | 0 |

$$-128 + 64 + 16 + 8 = -40$$

*The most significant bit is worth  $-128$ , so  $11011000 = -128 + 64 + 16 + 8 = -40$*

To read a negative two's complement number, just add the place values (the MSB counts as  $-128$ ). The range of an 8-bit two's complement number is  $-128$  to  $+127$ .

## Representing text

Computers store text by giving every character a number, then storing that number in binary. The set of characters a computer can use, together with their numbers, is a **character set** 字符集.

- **ASCII** uses 7 bits per character, so it has 128 different characters. This is enough for English letters, digits and common symbols.
- **Unicode** uses more bits per character. It can represent far more characters — many languages, plus symbols and **emoji** 表情符号.

Because Unicode has more characters, it needs more bits per character than ASCII, so the same text takes more storage 存储.

*ASCII uses 7 bits for 128 characters; Unicode uses more bits for far more characters but more storage*

## Representing sound

A **sound wave** 声波 is smooth and always changing. To store it, the computer measures the height of the wave at regular moments. This is called **sampling** 采样, and each measurement is a sample.

$$\text{sample rate} = \text{samples/s} \cdot \text{Nyquist} \geq 2f_{\max}$$

*Sampling records the wave's height (amplitude) at regular moments*

- **sample rate** 采样率 is the number of samples taken each second (measured in Hz).
- **sample resolution** 采样分辨率 is the number of bits used for each sample. The height of the wave at a sample point is its **amplitude** 振幅.

A higher sample rate and a higher sample resolution give a more accurate recording, but a larger file.

## Representing images

A computer image is made of a grid of small dots called **pixels** 像素.

resolution =  $8 \times 8$  pixels

*A bitmap is a grid of pixels; the resolution is how many pixels it has*

- **resolution** 分辨率 is the number of pixels in the image (for example  $1920 \times 1080$ ).
- **colour depth** 颜色深度 is the number of bits used to store the colour of each pixel.

A higher resolution and a higher colour depth give a better-quality image, but a larger file.

# Measuring data storage

Data storage is measured in the units below. A nibble is 4 bits and a byte is 8 bits; from the kibibyte upward, each unit is 1024 times the one before it (because  $1024 = 2^{10}$ , which fits binary).

| Unit           | Equals          |
|----------------|-----------------|
| bit            | a single 0 or 1 |
| nibble         | 4 bits          |
| byte           | 8 bits          |
| kibibyte (KiB) | 1024 bytes      |
| mebibyte (MiB) | 1024 KiB        |
| gibibyte (GiB) | 1024 MiB        |
| tebibyte (TiB) | 1024 GiB        |
| pebibyte (PiB) | 1024 TiB        |
| exbibyte (EiB) | 1024 PiB        |

*Hard-disk platters: storage is measured in bytes — knowing file size needs width  $\times$  height  $\times$  colour depth for images*

## Calculating file size

**Image file size** (in bits) = resolution  $\times$  colour depth = width  $\times$  height  $\times$  colour depth.

Example: an image is  $1024 \times 1024$  pixels with a colour depth of 2 bytes (= 16 bits).

- $\text{bits} = 1024 \times 1024 \times 16 = 16\,777\,216$  bits
- $\text{bytes} = \div 8 = 2\,097\,152$  bytes
- $\text{KiB} = \div 1024 = 2048$  KiB
- $\text{MiB} = \div 1024 = 2$  MiB

**Sound file size** (in bits) = sample rate  $\times$  sample resolution  $\times$  length in seconds.

Always divide by 1024 (not 1000) to change to KiB, MiB and so on. Give your answer in the unit the question asks for.

**Worked example.** A sound is recorded for 30 seconds at a sample rate of 8,000 Hz with a sample resolution of 16 bits. Find the file size in kibibytes (KiB).

- $\text{bits} = 8\,000 \times 16 \times 30 = 3\,840\,000$  bits
- $\text{bytes} = 3\,840\,000 \div 8 = 480\,000$  bytes
- $\text{KiB} = 480\,000 \div 1024 \approx 469$  KiB

## Compression

**Compression** 压缩 makes a file smaller. A smaller file:

- uses less storage space,
- needs less **bandwidth** 带宽 (the amount of data a connection can carry),
- takes a shorter time to send (a shorter **transmission** 传输 time).

There are two types.

## Lossless compression

**Lossless** 无损 compression makes the file smaller with **no permanent loss** of data. The original file can be rebuilt exactly.

One method is **run-length encoding** 行程编码 (RLE). It replaces a run of repeated values with one copy of the value and a count of how many times it repeats. For example WWWWWW (8 whites) is stored as "8 W". This works well when data has many repeats.

*Run-length encoding stores each run once as a count and a value*

## Lossy compression

**Lossy** 有损 compression makes the file much smaller by **permanently removing** some data. The removed data cannot be got back. For example:

- reducing the resolution or colour depth of an image,
- reducing the sample rate or sample resolution of a sound.

Use lossless when you must keep every detail (text and program files). Use lossy for photos, music and video, where a small loss of quality is worth a much smaller file.

## Exam tips

- Convert denary → binary by subtracting the place values (128, 64, 32 ...); binary → denary by adding the place values that hold a 1.
- To convert to hex, group the binary into **nibbles** of 4 bits from the right; each nibble is exactly one hex digit.
- **Overflow** happens when a result needs more bits than the register has (an 8-bit register only holds 0–255), so the extra bit is lost.

- File size in bits: for an image, width  $\times$  height  $\times$  colour depth; for sound, sample rate  $\times$  resolution  $\times$  seconds. Divide by 8 for bytes, then by 1024 for each larger unit.
- **Lossless** compression keeps every bit (text; run-length encoding); **lossy** permanently removes data (photos, music) for a much smaller file.
